ABSTRACT

The replication crisis has led many researchers to preregister their hypotheses and data analysis plans before collecting data. A widely held view is that preregistration is supposed to limit the extent to which data may influence the hypotheses to be tested. Only if data have no influence an analysis is considered confirmatory. Consequently, many researchers believe that preregistration is only applicable in confirmatory paradigms. In practice, researchers may struggle to preregister their hypotheses because of vague theories that necessitate data-dependent decisions (aka exploration). We argue that preregistration benefits any study on the continuum between confirmatory and exploratory research. To that end, we formalize a general objective of preregistration and demonstrate that exploratory studies also benefit from preregistration. Drawing on Bayesian philosophy of science, we argue that preregistration should primarily aim to reduce uncertainty about the inferential procedure used to derive results. This approach provides a principled justification of preregistration, separating the procedure from the goal of ensuring strictly confirmatory research. We acknowledge that knowing the extent to which a study is exploratory is central, but certainty about the inferential procedure is a prerequisite for persuasive evidence. Last, we discuss the implications of these insights for the practice of preregistration.

KEYWORDS

preregistration; confirmatory analyses; exploratory analyses; hypothesis testing; bayesian; open science

The scientific community has long pondered the vital distinction between exploration and confirmation, discovery and justification, hypothesis-generating and hypothesis-testing, or prediction and postdiction (Hoyningen-Huene 2006; Shmueli 2010, Nosek et al. (2018)). There is a broad consensus that both approaches are necessary for science to progress; exploration for making new discoveries and confirmation for exposing these discoveries to potential falsification and assess in how far it has been corroborated. Mistaking exploratory findings for empirically confirmed results inflates the the likelihood of believing that there is evidence for a given explanation even if it is false. A variety of practices, such as researchers' degrees of freedom together with researchers' hindsight bias or naive p-hacking have led to such mistakes

becoming commonplace yet unnoticed for a long time. Recognizing them has led to a crisis of confidence in the empirical sciences (Ioannidis 2005), and psychology in particular (Open Science Collaboration 2015). As a response to the crisis, more and more researchers preregister their data collection and analysis plans in advance of the study (Nosek et al. 2018). They do so to stress the predictive nature of their registered statistical analyses; often with the hopes of obtaining a label that marks the study as “confirmatory”. Indeed, rigorous application of preregistration prevents researchers from reporting a set of results produced by an arduous process of trial and error as a simple confirmatory story (Wagenmakers et al. 2012) while keeping low false-positive rates. This promise of a clear distinction between confirmation and exploration has obvious appeal to many who already accepted the practice. Still, the majority of empirical researchers do not routinely preregister their studies. One reason may be that some do not find that the theoretical advantages outweigh the practical hurdles, such as specifying every aspect of a theory in advance. We believe that we can reach a greater acceptance of preregistration by explicating a more general objective of preregistration that benefits all kinds of studies, even those that allow data-dependent decisions.

One goal of preregistration that has received widespread attention, is to clearly distinguish confirmatory from exploratory research (Mellor and Nosek 2018; Nosek et al. 2018; Wagenmakers et al. 2012; Simmons, Nelson, and Simonsohn 2021; Bakker et al. 2020). In such narrative, preregistration is justified by a confirmatory research agenda. However, two problems emerge under closer inspection. First, many researcher do not subscribe to a purely confirmatory research agenda. Second, it is not necessary to strictly map the categories preregistered vs. non-preregistered onto the categories confirmatory vs. exploratory research.

Obviously, researchers can conduct confirmatory research without preregistration—though it might be difficult to convince other researchers of the confirmatory nature of their research, that is, that they were free of cognitive biases, made no data-dependent decisions whatsoever, etc. The opposite, i.e., preregistered but not strictly confirmatory studies, are also commonplace (Dwan et al. 2008; Chan et al. 2004; Silagy, Middleton, and Hopewell 2002). Researchers may apply two strategies to evade the self-imposed restrictions of preregistrations: writing a loose preregistration to begin with (Stefan and Schönbrodt 2022) or deviating from the preregistration afterwards. Both strategies may be used for sensible scientific reasons or with the self-serving intent of generating desirable results. Thus, insisting on equating preregistration and confirmation has led to the criticism that, all things considered, preregistration is actually harmful, and neither sufficient nor necessary for doing good science (Szollosi et al. 2020; Pham and Oh 2021).

We argue that such criticism is not directed against preregistration itself but against a justification through a confirmatory research agenda (Wagenmakers et al. 2012). When researchers criticize preregistration as being too inflexible to fit their research question, they often simply acknowledge that their research goals are not strictly confirmatory. Forcing researchers into a confirmatory research agenda does not only imply changing *how* they investigate but also *what* research questions. However reasonable such a move is, changing core beliefs of a large community is much harder than convincing them that a method is well justified. We therefore attempt to disentangle the *methodological* goals of preregistration from the *ideological* goals of confirmatory science. It might be that psychology needs more confirmatory studies but preregistration can be useful for any kind of study in the continuum between purely confirmatory and fully exploratory.

To form such objective for preregistration, we first introduce some tools of Bayesian philosophy of science and map the exploration/confirmation distinction onto a dimensional quantity we call “theoretical risk” (a term borrowed from Meehl 1978, but formalized as the probability of proving a hypothesis wrong, if it does not hold), which is inversely related to the type-I error rate.

We then outline two interpretations of how preregistration impacts theoretical risk. The first interpretation corresponds to the traditional application of preregistration to research paradigms that focus on confirmation by maximizing the theoretical risk or equivalently by limiting type-I error (when dichotomous decisions about theories are an inferential goal). The second interpretation is our main contribution and demonstrates the broad applicability of preregistration to both exploratory and confirmatory studies that are implemented as preregistered or have undergone changes after preregistration. We argue that the classic view on the utility of preregistration can be interpreted as maximization of theoretical risk, which is reduced by researchers’ degrees of freedom, p-hacking, and such. Importantly, we argue that theoretical risk is not necessarily directly maximized by preregistration, but rather the uncertainty in judging the theoretical risk is minimized.

To arrive at this interpretation, we rely on three arguments. The first is that theoretical risk is vital for judging evidential support for theories. The second argument is that the theoretical risk for a given study is generally uncertain. The third and last argument is that this uncertainty is reduced by applying preregistration. We conclude that because preregistration decreases uncertainty about the theoretical risk, which in turn increases our expectation to gain evidence for a theory, preregistration is potentially useful for any kind of study, no matter how exploratory.

1. Epistemic value and the Bayesian rationale

Let us start by defining what we call expected epistemic value. If researchers plan to conduct a study, they usually hope it will change their assessment of some theory’s verisimilitude (Niiniluoto 1998). In other words, they hope to learn something from conducting the study. The amount of knowledge researchers gain from a particular study concerning the verisimilitude of a specific theory (which itself is an ontological concept) is what we call epistemic value. Researchers cannot know what exactly they will learn from a study before they have run it. However, they can develop an expectation that helps them decide which study to conduct in what manner. This expectation is what we term expected epistemic value. To make our three arguments, we must assume three things about this estimation process and how it relates to what studies (preregistered vs not preregistered) to conduct.

1. Researchers judge the evidence for or against a hypothesis rationally.
2. They expect other researchers to apply a similar rational process.
3. They try to maximize the expected epistemic value for other researchers.

The assumption of rationality can be connected to Bayesian reasoning and leads to our adoption of the framework. Our rationale is as follows. Researchers who decide to conduct a certain study are actually choosing a study to bet on. They have to “place the bet” by conducting the study, therefore, invest resources and stand to gain epistemic value with some probability. This conceptualization of choosing a study as a betting problem allows us to apply a “Dutch Book” argument (Christensen 1991). This argument states that any better must follow the axioms of probability to avoid

being “irrational,” i.e., accepting bets that lead to sure losses. Fully developing a Dutch book argument for this problem requires careful consideration of what kind of studies to include as possible bets, defining a conversion rate from the stakes to the reward, and modelling what liberties researchers have in what studies to conduct. Without deliberating these concepts further, we find it persuasive that researchers should not violate the axioms of probability if they have some expectation about what they stand to gain with some likelihood from conducting a study. The axioms of probability are sufficient to derive the Bayes formula, on which we will heavily rely for our further arguments. The argument is not sufficient, however, to warrant conceptualizing the kind of epistemic value we reason about in terms of posterior probability; that remains a leap of faith. However, the argument applies to any reward function that satisfies the “statistical relevancy condition” (Salmon 1970; Fetzer 1974). That is, evidence only increases epistemic value for a theory, if the evidence is more likely to observe under the theory than without it.

Please note that our decision to adopt this aspect of the Bayesian philosophy of science does not imply anything about the statistical methods researchers use. In fact, this conceptualization is intentionally reductionistic to be compatible with a wide range of philosophies of science and statistical methods researchers might subscribe to.

2. Epistemic value and theoretical risk

Our first argument is that theoretical risk is crucial for judging evidential support for theories. Put simply, risky predictions create persuasive evidence if they turn out to be correct. This point is crucial because we attribute much of the appeal of a confirmatory research agenda to this fact.

Let us make some simplifying assumptions and define notation. We restrict ourselves to evidence of a binary nature (either it was observed or not) since continuous evidence would lead to some quite involved derivations. We denote the probability of a hypothesis before observing evidence as $P(H)$ and its complement as $P(\neg H) = 1 - P(H)$. The probability of observing evidence under some hypothesis is $P(E|H)$. We can calculate the probability of the hypothesis after observing the evidence with the help of the Bayes formula:

$$P(H|E) = \frac{P(H)P(E|H)}{P(E)} \quad (1)$$

The posterior probability $P(H|E)$ is of great relevance since it is often used directly or indirectly as a measure of corroboration of a hypothesis. In the tradition of Carnap, in its direct use, it is called corroboration as firmness; in its relation to the a priori probability $P(H)$, it is called increase in firmness (Carnap 1950, preface to the 1962 edition). As noted before, we concentrate on posterior probability as a measure of epistemic value, since no measure shows universally better properties than others. However, it is generally expected that any measure of corroboration increases monotonically with an increase in posterior probability $P(H|E)$ and our argument applies to those measures as well. We assume that any measure shows gain if, and only if, evidence is observed assuming $P(E|H) > P(E|\neg H)$. This assumption is sometimes called statistical relevance condition (Salmon 1970; Fetzer 1974).

In short, we want to increase posterior probability $P(H|E)$. Increases in posterior probability $P(H|E)$ are associated with increased epistemic value, for which we want to maximize the expectation. So how can we increase posterior probability? The Bayes formula yields three components that influence corroboration, namely $P(H)$, $P(E|H)$ and $P(E)$. The first option leads us to the unsurprising conclusion that higher a priori probability $P(H)$ leads to higher posterior probability $P(H|E)$. If a hypothesis is more probable to begin with, observing evidence in favor will result a more corroborated hypothesis, all else equal. However, the prior probability of a hypothesis is nothing our study design can change. The second option is similarly commonsensical; that is, an increase in $P(E|H)$ leads to higher posterior probability $P(H|E)$. $P(E|H)$ is the probability of obtaining evidence for a theory, when the theory holds. We call this probability of detecting evidence given that the theory holds “detectability.” Consequently, researchers should ensure that their study design allows them to find evidence for their hypothesis, in case it is true. When applied strictly within the bounds of null hypothesis testing, detectability is equivalent to power (or the inverse of type-II error rate). However, while detectability is of great importance for study design, it is not directly relevant to the objective of preregistration. Thus, $P(E)$ remains to be considered. Since $P(E)$ is the denominator, increasing it will decrease the posterior probability: The more unlikely it is to observe evidence, the more it increases the probability of the hypothesis if we do observe it. In other words, high risk, high reward.

If we equate riskiness with a low probability of obtaining evidence, the Bayesian rationale perfectly aligns with the observation that risky predictions lead to persuasive evidence. This tension between high risk leading to high reward is central to our consideration of preregistration. A high-risk, high-reward strategy is bound to result in many losses that are eventually absorbed by the high gains. Sustaining many “failed” studies is not exactly aligned with the incentive structure under which many, if not most, researchers operate. Consequently, researchers have an incentive to appear to take more risks than they actually do, which misleads their readers to give their claims more credence than they deserve. It is at this juncture that the practice and mispractice of preregistration comes into play. We argue that the main function of preregistration is to enable proper judgment of the riskiness of a study.

To better understand how preregistrations can achieve that, let us take a closer look at what factors contribute to $P(E)$. Using the law of total probability, we can split $P(E)$ into two terms:

$$P(E) = P(H)P(E|H) + P(\neg H)P(E|\neg H) \quad (2)$$

We already have noted that there is not much to do about prior probability ($P(H)$), and hence its counter probability $P(\neg H)$, and that it is common sense to increase detectability $P(E|H)$. The real lever to pull is, therefore, $P(E|\neg H)$. This probability tells us how likely it is that we find evidence in favor of the theory when in fact, the theory is not true. Its counter probability $P(\neg E|\neg H) = 1 - P(E|\neg H)$ is what we call “theoretical risk”, because it is the risk a theory takes on in predicting the occurrence of particular evidence in its favour. We “borrow” the term from Meehl (1978), though he has not assigned it to the probability $P(\neg E|\neg H)$. Kukla (1990) argued that the core arguments in Meehl (1990) can be reconstructed in purely Bayesian framework. However, while he did not name $P(\neg E|\neg H)$ but did suggest that Meehl (1978) used the term “very strange coincidence” for a small $P(E|\neg H)$ which would imply that

$P(\neg E|\neg H)$ can be related to or even equated to theoretical risk.

Let us note some interesting properties of theoretical risk $P(\neg E|\neg H)$. First, increasing theoretical risk leads to higher posterior probability $P(H|E)$, our objective. Second, if the theoretical risk is smaller than detectability $P(E|H)$ it follows that the posterior probability must decrease when observing the evidence. If detectability exceeds theoretical risk, the evidence is less likely under the theory than it is when the theory does not hold. Third, if the theoretical risk equals zero, then posterior probability is at best equal to prior probability but only if detectability is perfect ($P(H|E) = 1$). In other words, observing a sure fact does not lend credence to a hypothesis.

The last statement sounds like a truism but is directly related to Popper’s seminal criterion of demarcation. He stated that if it is impossible to prove that a hypothesis is false ($P(\neg E|\neg H) = 0$, theoretical risk is zero), it cannot be considered a scientific hypothesis (Popper 2002, p. 18). We note these relations to underline that the Bayesian rational we apply here is able to reconstruct many commonly held views on riskiness and epistemic value.

Both theoretical risk $P(\neg E|\neg H)$ and detectability $P(E|H)$ aggregate uncountable influences, otherwise they could not model the process of evidential support for theories. To illustrate the concepts we introduced up to here, consider the following example of a single theory and three experiments that may test it. The experiments were created to illustrate how they may differ in their theoretical risk and detectability. Suppose the primary theory is about the cognitive phenomenon of “insight.” For the purpose of illustration, we define it, with quite some hand-waving, as a cognitive abstraction that allows agents to consistently solve a well-defined class of problems. We present the hypothesis that the following problem belongs to such a class of insight problems:

Use five matches (IIII) to form the number eight.

We propose three experiments that differ in theoretical risk and detectability. All experiments take a sample of ten psychology students. We present the students with the problem for a brief span of time. After that, the three experiments differ as follows:

1. The experimenter gives a hint that the problem is easy to solve when using Roman numerals; if all students come up with the solution, she records it as evidence for the hypothesis.
2. The experimenter shows the solution “IX” and explains it; if all students come up with the solution, she records it as evidence for the hypothesis.
3. The experimenter does nothing; if all students come up with the solution, she records it as evidence for the hypothesis.

We argue that experiment 1 has high theoretical risk $P(\neg E_1|\neg H)$ and high detectability $P(E_1|H)$. If “insight” has nothing to do with solving the problem ($\neg H$), then presenting the insight that Roman numerals could be used, should not lead to all students solving the problem ($\neg E_1$); the experiment therefore has high theoretical risk $P(\neg E_1|\neg H)$. Conversely, if insight is required to solve the problem (H), then it is likely to help all students to solve the problem (E_1), the experiment therefore has high detectability $P(E_1|H)$. The second experiment, on the other hand, has low theoretical risk $P(\neg E_2|\neg H)$. Even if “insight” has nothing to do with solving the problem ($\neg H$), there are other plausible reasons for observing the evidence (E_2), because the students could simply copy the solution, without having any insight. With regard to detectability, experiments 1 and 2 differ in no obvious way. Experiment 3, however, also has low detectability. It is unlikely that all students come up with the correct solution in a short time (E_3), even if insight is required (H) experiment 3 therefore

has low detectability $P(E_3|H)$. The theoretical risk, however, is also low in absolute terms, but high compared to the detectability (statistical relevancy condition is satisfied). In the unlikely event that all 10 students place their matches to form the Roman numeral VIII (E_3), it is probably due to insight (H) and not by chance $P(\neg E_3|\neg H)$. Of course, in practice, we would allow the evidence to be probabilistic, e.g., relax the requirement of “all students” to nine out of ten students, more than eight, and so forth.

As argued earlier, the remainder of the paper will focus on binary, non-probabilistic evidence to keep the mathematical notation as simple as possible. We discuss the relation between statistical methods and theoretical risk in the Statistical Methods section.

3. Preregistration as a means to increase theoretical risk?

Having discussed that increasing the theoretical risk will increase the epistemic value, it is intuitive to task preregistration with maximizing theoretical risk, i.e., a confirmatory research agenda. Indeed, limiting the type-I error rate is commonly stated as a goal of preregistration (Nosek et al. 2018; Oberauer 2019; Rubin 2020). We argue that while such a conclusion is plausible, we must first consider at least two constraints that place an upper bound on the theoretical risk.

First, the theory itself limits theoretical risk: Some theories simply do not make risky predictions, and preregistration will not change that. Consider the case of a researcher contemplating the relation between two sets of variables. Suppose each set is separately well studied, and strong theories tell the researcher how the variables within the set relate. However, our imaginary researcher now considers the relation between these two sets. For lack of a better theory, they assume that some relation between any variables of the two sets exists. This is not a risky prediction to make in psychology, even without statistical issues like alpha inflation (Orben and Lakens 2020). However, we would consider it a success if the researcher would use the evidence to develop a more precise (and therefore risky) theory, e.g., by specifying which variables from one set relate to which variables from the other set, to what extent, in which direction, with which functional shape, etc. We will later show that preregistration increases the degree of belief in the further specified theory, though it remains low till being substantiated by testing it again. The point, however, is that we want to show that preregistration increases the expected epistemic value regardless of the theory being tested.

Second, available resources limit theoretical risk. Increasing theoretical risk $P(\neg E|\neg H)$ will usually decrease detectability $P(E|H)$ unless more resources are invested. In other words, one cannot increase power while maintaining the same type-I error rate without increasing the invested resources. Tasking preregistration with an increase in theoretical risk makes it difficult to balance this trade-off. Mindlessly maximizing theoretical risk would either never produce evidence or require huge amounts of resources.

4. Uncertainty about theoretical risk

We have established that higher theoretical risk leads to more persuasive evidence. In other words, we have reconstructed the interpretation that preregistrations sup-

posedly work by restricting the researchers, which in turn increases the theoretical risk (or equivalently limits the type-I error rate) and thereby creates more compelling evidence. Nevertheless, there are trade-offs for increasing theoretical risk. Employing a mathematical framework allows us to navigate the trade-offs more effectively and move towards a second, more favorable interpretation. To that end, we incorporate uncertainty into our framework.

4.1. *Statistical methods*

One factor that is known without much uncertainty is the contribution of statistical methods to theoretical risk. Theoretical risk is deeply connected with statistical methods, because it is the inverse of $P(E|\neg H)$. $P(E|\neg H)$ is equivalent to the type-I error rate, if you consider the overly simplistic case where the research hypothesis is equal to the statistical alternative hypothesis, because then the null hypothesis is $\neg H$. Because many researchers are familiar with the type-I error rate, it can be helpful to remember this connection to theoretical risk. Researchers who choose a smaller type-I error rate can be more sure of their results, if significant, because the theoretical risk is higher. However, the research hypothesis seldomly equals the statistical null hypothesis, and therefore, the relation between statistical type-I error rate and theoretical risk should not be overinterpreted. We argue that theoretical risk (and hence its inverse, $P(E|\neg H)$) also encompasses factors outside the statistical realm, most notably the study design and broader analytical strategies.

Statistical methods stand out among these factors because we have a large toolbox for assessing and controlling their contribution to theoretical risk. Examples of our ability to exert this control are the setting of type-I error rate, the use of corrected fit measures (i.e., adjusted R^2), information criteria, or cross-validation in machine learning. These tools help us account for biases in statistical methods that increase the likelihood of signifying results even when there are none $P(E|\neg H)$.

The point is that the contribution of statistical methods to theoretical risk can be formally assessed. For many statistical models it can be analytically computed under some assumptions. For those models or assumptions where this is impossible, one can employ Monte Carlo simulation to estimate the contribution to theoretical risk. The precision with which statisticians can discuss contributions to theoretical risk has lured the community concerned with research methods into ignoring other factors that are much more uncertain. We cannot hope to resolve this uncertainty; but we have to be aware of its implications. These are presented in the following.

4.2. *Sources of Uncertainty*

As we noted, it is possible to quantify how statistical models affect the theoretical risk based on mathematical considerations and simulation. However, other factors in the broader context of the study are much harder to quantify. If one chooses to focus only on the contribution of statistical methods to theoretical risk, one is bound to overestimate it. Take, for example, a t-test of mean differences in two samples. Under ideal circumstances (assumption of independence, normality of residuals, equal variance), it stays true to its type-I error rate. However, researchers might do many very reasonable things in the broader context of the study that affect theoretical risk: They might exclude outliers, choose to drop an item before computing a sum score, broaden, enlarge their definition of the population to be sampled, translate their questionnaires

into a different language, impute missing values, or any number of other things. All of these decisions carry a small risk that they increase the likelihood of obtaining evidence despite the underlying research hypothesis being false. Even if the t-test itself perfectly maintains its type I error rate, these factors influence $P(E|\neg H)$. While, in theory, these factors may leave $P(E|\neg H)$ unaffected or even decrease it, we argue that this is not the case in practice. Whether researchers want to or not, they continuously process information about how the study is going, except under strict blinding. While one can hope that processing this information does not affect their decision making either way, this cannot be secured. We, therefore, conclude that statistical properties only guarantee a lower bound for theoretical risk. The only thing we can conclude with some certainty is that theoretical risk is not higher than what the statistical model guarantees without knowledge about the other factors at play.

4.3. *The effects of uncertainty*

Before we ask how preregistration influences this uncertainty, we must consider the implications of being uncertain about the theoretical risk. Within the Bayesian framework, this is both straightforward and insightful. To get an expectation, we express uncertainty as a probability distribution and then integrate over it:

$$\mathbb{E}(p(H|E)) = \int \frac{p(H)p(E|H)}{p(H)p(E|H) + p(\neg H)p(E|\neg H)} d\mathbb{P}(p(E|\neg H)) \quad (3)$$

To illustrate the effect of uncertainty, let $p(E|H) = 0.8$ (e.g., power of 80%) and $p(H) = 0.1$ and assume a uniform distribution for theoretical risk $p(\neg E|\neg H)$ of the form:

$$f(x) = \begin{cases} \frac{1}{\tau} & \text{for } 0 \leq x \leq \tau, \\ 0 & \text{for } x < 0 \text{ or } x > \tau \end{cases} \quad (4)$$

Where τ is the upper bound of theoretical risk (e.g., 0.95 for a statistical model with a nominal type-I error rate of 5%). We chose this uniform distribution to capture our statement that a statistical model only guarantees an upper bound to theoretical risk (and since it is a probability the lower bound is 0) as it is the maximum entropy distribution under this assumption and conforms therefore to our Bayesian framework (Giffin and Caticha 2007).

Figure 1 shows exemplary the effect of theoretical risk (x-axis) on the posterior probability (y-axis) being fully certain (solid line) or fully uncertain (dashed line) about the theoretical risk of a study. Neither absolute certainty nor uncertainty are realistic scenarios but represent the boundary conditions into which all realistic conditions fall. Depending on how uncertain we are about the theoretical risk a study took on, our expectation the gained epistemic value varies considerably. Mathematically, uncertainty about theoretical risk is expressed through the variance (or rather entropy) of the distribution. Generally, we expect that increases in uncertainty (expressed as more entropic distributions) lead to a decreased expected epistemic value.

The argument for a confirmatory research agenda is that by increasing theoretical risk we increase expected epistemic value, i.e., moving to the right on the x-axis in

Figure 1. Posterior Probability (corroboration as firmness) as a function of theoretical risk τ , where τ is either certain (solid line) or maximally uncertain (dotted line).

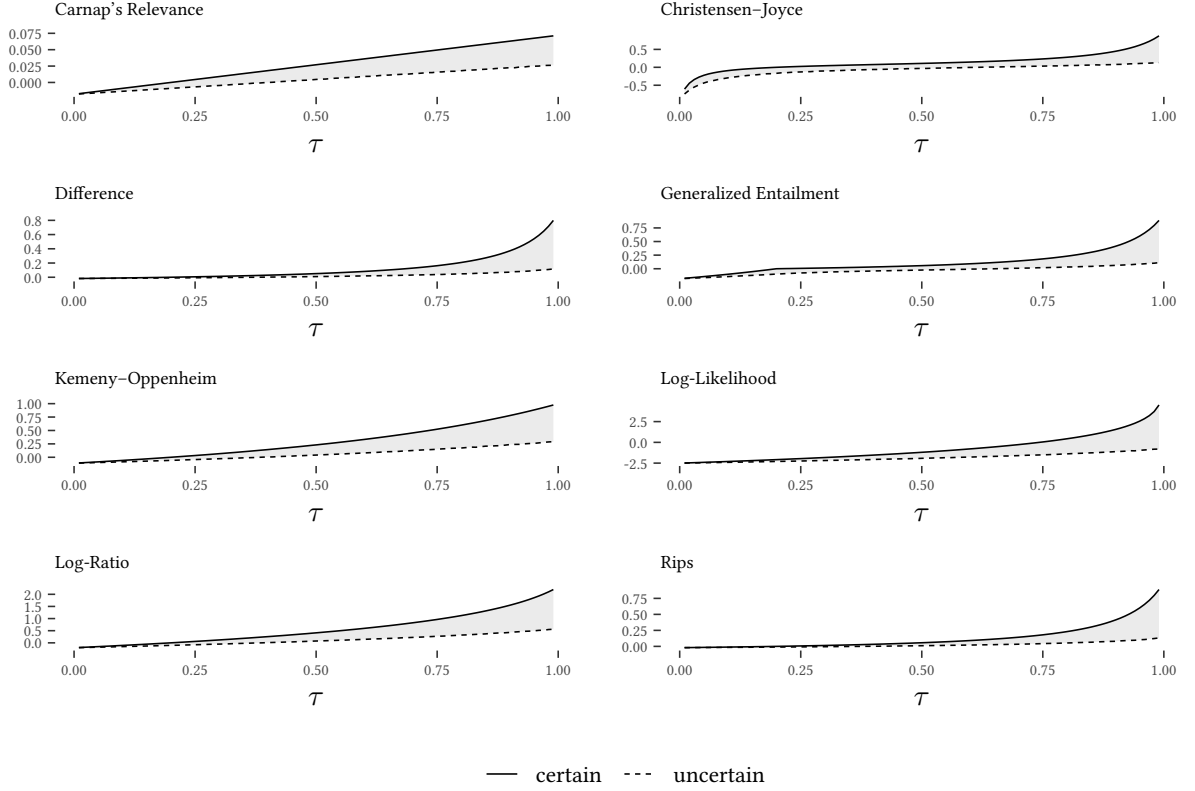

Figure 2. Several measures for corroboration as increase in firmness as a function of τ , where τ is either certain (solid line) or maximally uncertain (dotted line).

Figure 1 increases posterior probability (on the y-axis). However, if a hypothesis in a certain study has low theoretical risk, there is not much researchers can do about it. However, studies do not only differ by how high the theoretical risk is but also how certain the recipient is about the theoretical risk. A study that has a very high theoretical risk, e.g., 1% chance that if the hypothesis is wrong, evidence in its favor will be observed, i.e., alpha error, but has also maximum uncertainty will result in a posterior probability of 21%, while the same study with maximum certainty will result in 90% posterior probability. The other factors (detectability, prior beliefs, measure of epistemic value) and, therefore, the extend of the benefit very of course with the specifics of the study. Crucially, even studies with some exploratory aspects benefit from preregistration, e.g., in this scenario with a $\tau = 0.8$, so false positive rate of 0.2, moving from uncertain to certain increases the posterior by a factor of 2.09.

5. Preregistration as a means to decrease uncertainty about the theoretical risk

We hope to have persuaded the reader to accept two arguments: First, the theoretical risk is important for judging evidential support for theories. Second, the theoretical risk is inherently uncertain and the degree of uncertainty diminishes the persuasiveness of the gathered evidence. The third and last argument is that preregistrations reduce this uncertainty. Following the last argument, a preregistered study is represented by the solid line (certainty about theoretical risk) and a study that was not preregistered

is more similar to the dashed line (maximally uncertain about theoretical risk) in Figure 1/2.

Recollect, our three assumptions:

1. Researchers judge the evidence for or against a hypothesis rationally.
2. They expect other researchers to apply the same rational process.
3. All else being equal, researchers try to increase the expected epistemic value for other researchers.

The point we make with these assumptions is that researchers aim to persuade other researchers, the readers of their articles. We have to remember that the process of weighing evidence for or against a theory extends beyond the original authors to all the people they hope to persuade. Unfortunately, the case for lack of insight into the myriad of factors that influence theoretical risk is particularly strong for the reader of a resulting article (or, more generally, the consumer of the research product). While the authors may have deep insight into what they did and how it might influence the theoretical risk they took, their readers have much greater uncertainty about these factors. In particular, they never know which relevant factors the authors of a given article failed to disclose, intentionally or not. From the perspective of an ultimate sceptic, they may claim maximum uncertainty.

Communicating clearly how the authors gathered the data and consequently analyzed it to arrive at the evidence they present is crucial for judging the theoretical risk they took. Preregistrations are ideal to communicate just that, because any description after the fact is suspect to be incomplete. For instance, the authors could have decided to exclude a number of analytic strategies they tried out. That is not to say that every study that was not-preregistered was subjected to practices of p hacking. The point is, that we cannot exclude this and innumerable possibilities and, hence, are left uncertain. This uncertainty is drastically reduced, if the researchers have described what they intended to do beforehand, and then report that they did exactly that. In that case, the readers can be certain, that they have received a complete account of the situation. They still might be uncertain about the actual theoretical risk the authors took, but to a much smaller extend than if the study would not have been preregistered. Remaining sources of uncertainty might be unfamiliarity with statistical methods or experimental paradigms used, the probability of an implementation error in the statistical analyses, a bug in the software used for analyses, etc. In any case a well written preregistration should aim to reduce the uncertainty about the theoretical risk and hence increase the persuasiveness of evidence. A study with a perfect preregistration will, therefore, resemble the solid line in Figure 1/2. Crucially, perfect means here that the theoretical risk can be judged with low uncertainty, not the the theoretical risk is necessarily high.

6. Discussion

To summarize, we showed that higher theoretical risk and lower uncertainty about theoretical risk lead to higher expected epistemic value across a variety of measures. The former result, that increasing theoretical risk leads to higher expected epistemic value, reconstructs the appeal of confirmatory research. However, theoretical risk is something researcher have only limited control over, e.g., theories are often vague and illdefined, resources are limited, and increasing theoretical risk usually decreases detectability (a special instance of this trade off is the well known tension between

alpha error and power). Before researchers may preregister a confirmatory study with high theoretical risk, they must ensure that they are able to conduct a confirmatory study. Researchers must develop theories sufficiently and then have the resources to adequately balance detectability against theoretical risk.

A preregistration may at most help to invest some time into developing more specific, hence riskier, implications of a theory. But for a confirmatory science it will not be enough to preregister. This undertaking requires action from the whole research community (Lishner 2015). Incentive structures must be more willing to evaluate not the outcomes of a study but the rigor with which it was conducted (Cagan 2013; Schönbrodt et al. 2022). Journal editors could encourage theoretical developments and be willing to accept registered reports (Fried 2020a,b; van Rooij and Baggio 2020, 2021). Funding agencies should demand an explicit statement about theoretical risk in relation to detectability and must be willing to provide the necessary resources to reach adequate levels of both (Koole and Lakens 2012).

Our later result, on the importance of preregistration for minimizing uncertainty, has two important implications. The first is, that even if all imaginable actions regarding promoting higher theoretical risk are taken, confirmatory research should be preregistered. Otherwise the uncertainty about the theoretical risk will diminish the advantage of confirmatory research. Second, even under less than ideal circumstances for confirmatory research, preregistration is beneficial. Preregistering exploratory studies increases the expected epistemic value by virtue of reducing uncertainty about theoretical risk. Nevertheless, exploratory studies will have a lower expected epistemic value than a more confirmatory study, if both are preregistered and have equal detectability.

Focusing on uncertainty reduction also explains two common practices of preregistration that do not align with a confirmatory research agenda. First, researchers seldomly predict precise numerical outcomes, instead they use preregistrations to describe the process that generates the results. Precise predictions would have very high theoretical risk (they are likely incorrect if the theory is wrong). A statistical procedure, may have high or low theoretical risk depending on the specifics of the model used. Specifying the process, therefore, is in line with the rational we propose here, but is incompatible with strictly confirmatory research.

Second, researchers often have to deviate from the preregistration and make data-dependent decisions outside of the preregistration. If the only goal of preregistration is to ensure confirmatory research, such changes are not justifiable. However, under our rational some changes may be justified. Any change would increase the uncertainty about the theoretical risk and may even decrease the theoretical risk. The changes still may be worthwhile, if the negative outcomes may be offset by an increase in detectability due to the change. Consider a preregistration that failed to specify what to do with missing values where the researchers subsequently encounter missings. In such case, the detectability is zero, since the data cannot be analyzed without a decision about how to handle the missing data. Any such decision would constitute a deviation from the preregistration. Furthermore, a reader cannot rule out that the researchers leveraged the decision to decrease theoretical risk, i.e., picking among all options the one that delivers the most beneficial results for the theory. Whatever decision they make, increased uncertainty about the theoretical risk is inevitable and the expected epistemic value is decreased compared to a world where they anticipated the need to deal with missing data. However, it is still justified to deviate. After all they have not anticipated the case and are left with a detectability of zero. Any decision will increase detectability to a non-zero value, likely offsetting the increase in uncertainty.

The researchers also may do their best to argue that the deviation was not motivated by increasing theoretical risk, thereby, decreasing the uncertainty. Maybe there is one decision that fits well with the theory or with the study design. Or, if there is no obvious candidate, the researchers could conduct a multiverse analysis of the available options to deal with missings to show the influence of the decision (Steegeen et al. 2016).

Using reduction in uncertainty as the objective for preregistration does not only explain some existing behavior, it allows to form recommendations to improve the practice of preregistration. Maybe most important, we now have a measure to differentiate a good preregistration from a bad one. In particular, a preregistration should be specific about the procedure that is intended to generate evidence for a theory. Such procedure may accommodate a wide range of possible data, i.e., it may be exploratory. The theoretical risk, however low, must be communicated clearly. Parts of the process left unspecified, imply uncertainty, which is what a preregistration should reduce. However, specifying procedures that can be expected to not work, will lead to deviation, and uncertainty later.

We have proposed a highly specific, yet practical preregistration procedure called preregistration as code (PAC) elsewhere (Peikert, van Lissa, and Brandmaier 2021). In a PAC, researchers use computer code instead of a verbal description. This enables a preregistrations to accommodate many different data patterns, yet is very specific about exactly how probable it is to generate evidence even when the theory does not hold (theoretical risk). To reduce the likelihood of deviation, we suggest that a PAC is tested on simulated or pilot data. Another advantage is that with a PAC, deviations from the preregistration can be isolated and inspected. This is possible because in a PAC, preregistration and final manuscript are different versions of the same dynamic document, which can be compared via version control. However, while PAC is ideally suited to reduce uncertainty about theoretical risk, other more traditional forms of preregistration are also suited to achieve this goal.

Contrary to what is widely assumed about preregistration, a preregistration is not necessarily a seal of confirmatory research. Confirmatory research would be much less persuasive without preregistration, but in our view preregistration simply communicates the extend of confirmation, i.e., theoretical risk, of a study. Clearly communicating theoretical risk is important because it reduces the uncertainty and hence increases expected epistemic value.

Notes

The materials for this article are available on GitHub (?). This version was created from git commit b042f02. The manuscript is available as preprint (?) and will be submitted to Philosophical Psychology.
